

The instrument sets the spectrum.
The prior only sets where it is cut.

The better fit is the worse answer.
The fit is not what fails; the observations are.

Mock tracer orbits in a softened point mass -- not a galaxy, not an instrument, not data. $N = 32$ orbits, softening = 0.2, 48 steps of $dt = 0.12$, entropy prior $\mu = 1e-08$, LBFGS for 1500 steps. Eigenvalues are the squared singular values of the whitened Jacobian, which is exact here and avoids the negative eigenvalues `eigvalsh` returns at this spectrum.

'effective' is `effective_parameters`, a local Gaussian-limit quantity, not a posterior. Both panels show both instruments: cropping either to the LOSVD alone turns the point into a capability claim and inverts it.
